

# Medicaid Insurance and Redistribution in Old Age

## Preliminary and Incomplete

Mariacristina De Nardi, Eric French, and John Bailey Jones\*

September 10, 2012

### Abstract

Medicaid was primarily designed to protect and insure the poor. However, the poor tend to live much shorter lifespans and thus incur much lower medical expenses before death. This paper measures Medicaid redistribution and its insurance benefits taking these dimensions of heterogeneity into account.

The Medicaid reciprocity rate for those at the bottom income quintile stays around 60%-70% throughout their retirement. In contrast, Medicaid reciprocity by higher-income retirees is much lower but increases by age, especially after age 90.

We find that the annuity value of Medicaid payments is a hump-shaped function of permanent income. People in the lowest 20% of the income distribution receive more or less the same the same average annual payments as those in the top 20%. Once one takes into account that the rich live longer, Medicaid is even less redistributive: in terms of present discounted value, the richest people receive more than the poorest ones, and the middle income people still benefit the most.

# 1 Introduction

a few things to think about.

1. can we show anything on how medicaid affects welfare (compensating variation calculations) and/or distorts consumption, medical spending and savings? I think we find that Medicaid is good for welfare, so it is interesting given that we would think that the distortions are large.
2. another interesting question is what groups of people would prefer an expansion of medicare (which gives a constant coinsurance rate) to other services such as nursing home care versus expansions of medicaid (which covers everything, but only when financially destitute).
3. We do have SSI benefits, conditional on other income. i'm not sure if this is a useful statistic to match.
4. another potentially useful set of statistics to match is about "what happens to people right before they wind up on medicaid?" for example, what happens to their assets, their out of pockets medical spending.
5. i am in the process of getting more meps data to measure how much middle income people benefit from medicaid. this of course will not have the nursing home people, but at least we will be able to match model to data for non-nursing home people, and we can see if medicaid expenses for nursing home people look plausible. hopefully this should be done soon.
6. would it be worth having data on

In the United States, a key public health insurance program for the elderly poor is Medicaid, a means-tested program that covers any medical expenses not picked up by other insurance programs. In this paper we analyze the insurance and redistributive properties of Medicaid during old age.

One force limiting Medicaid redistribution is that poor people tend to live shorter lives and to die before incurring large medical expenses. In contrast, richer people are more likely to live long and face expensive medical conditions, such as nursing home stays, when very old. Another force reducing Medicaid redistribution is that while Medicaid was initially designed to protect and insure the lifetime poor, it was later expanded to insure richer people impoverished by high medical expenses. For example, extended stays in a nursing home are generally not covered by other public or private insurance, even though nursing home care costs \$60,000 to \$75,000 a year (in 2005). Medicaid ends up financing 70% of nursing home residents (Kaiser Foundation [?]).

Using the Asset and Health Dynamics of the Oldest Old (AHEAD) dataset, we find that the average Medicaid reciprocity rate for old people in the bottom quintile of

the permanent income distribution is just under 70% and stays more or less constant throughout retirement. Medicaid reciprocity by higher-income retirees is significantly lower, but increases with age. Most notably, this increase tends to happen at more advanced ages for people in the highest permanent income quintiles, reflecting the fact that survivors with higher lifetime resources run out of savings (and thus qualify for Medicaid) later on in life.

To understand these mechanisms, we construct and estimate a life-cycle model of consumption and endogenous medical expenditure that accounts for Medicare, Supplemental Social Insurance (SSI) and Medicaid. Agents in the model face uncertainty about their health, lifespan, and medical needs (including nursing home stays). This uncertainty is partially offset by the insurance provided by the government and private institutions. Agents choose whether they want to apply for Medicaid if they are eligible, how much to save, and how to split their consumption between medical and non-medical goods.<sup>1</sup> We model two pathways to Medicaid, and allow the pathways to differ in generosity.

To appropriately evaluate redistribution, we allow for heterogeneity in wealth, permanent income (PI), health, gender, life expectancy, and medical needs. We also require our model to fit well across the entire income distribution, rather than simply explain mean or median behavior. Our model closely matches the life-cycle profiles of assets, out-of-pocket medical spending, and Medicaid reciprocity rates for elderly singles in different cohort and permanent income groups. It also generates an elasticity of total medical expenditures to co-payment changes that is close to the one estimated by Manning et al. [20] using the RAND Health Insurance Experiment.

We use our estimated model to compute how Medicaid payments vary by gender, permanent income, and health status. We find that the current Medicaid system provides different kinds of insurance to households with different resources. Households in the lower permanent income quintiles are much more likely to receive Medicaid transfers, but the transfers that they receive are on average relatively small. Households in the higher permanent income quintiles are much less likely to receive any Medicaid pay-outs, but when they do, these pay-outs are very big and correspond to severe and expensive medical conditions. Therefore, Medicaid is an effective insurance device for the poorest, but also offers valuable insurance to the rich by insuring them against catastrophic medical conditions.

We also compute the costs and benefits provided by Medicaid insurance in old age. Although there is a large literature on the health effects of these programs, and a smaller literature on the private markets that social insurance displaces, little is

---

<sup>1</sup>Three recent papers contain life-cycle models where the choice of medical expenditures also affects health outcomes. In addition to having different emphases, both papers model Medicaid in ways different from ours. Feng [20] models Medicaid as an insurance policy with no premiums and extremely low—possibly zero—co-payment rates. Fonseca et al. [21] assume that the consumption floor is invariant to medical needs (private conversation with Pierre-Carl Michaud). Ozkan [22] assumes that indigent individuals receive curative, but not preventative, care.

known about the insurance properties of social insurance.

Summing over agents' lives, our preliminary results show that at age 74 the expected annuity value of Medicaid benefits is a hump-shaped function of permanent income. People in the lowest 20% of the income distribution receive more or less the same average annual payment as those in the top 20%. Once one takes into account that the rich live longer, Medicaid is even less redistributive: in terms of present discounted value, the richest people receive more than the poorest ones, and the middle income people still benefit the most. **[To be completed.]**

## 2 Brief literature review

This paper is related to several previous papers on savings, health risks, and social insurance. Hurd [?] and Hurd, McFadden, Merrill [?] highlight the importance of accounting for the link between wealth and mortality risk when estimating life cycle models. Kotlikoff [?] stresses the importance of modeling health expenditures to understand precautionary savings.

Hubbard et al. [?] and Palumbo [?] solve early dynamic programming models of savings with medical expense risk and find that medical expenses have relatively small effects. The key reason why these papers underestimate medical spending risk is that the data sets available at that time had poor measures of medical spending and, in particular, were missing late in life medical spending and had poor measures of nursing home costs. Thus they underestimate the extent to which medical expenses rise with age and income.

Hubbard et al. [?] and Scholz et al. [?] argue that means-tested social insurance programs (in the form of a minimum consumption floor) provide strong incentives for low-income individuals not to save. Kopecky and Koleshikova [?] find that old-age medical expenses, and the coverage of these expenses provided by Medicaid, have large effects on aggregate capital accumulation. Brown and Finkelstein [?] develop a dynamic model of optimal savings long term care purchase decisions. They conclude that Medicaid could explain the lack of private long-term care insurance for about two-thirds of the wealth distribution. Consistent with this evidence, Brown et al. [?] exploit cross-state variation in Medicaid rules and also find significant crowding out."

Marshall, McGarry, and Skinner [?] revisit the question of whether out-of-pocket medical expenditures is a risk to financial security, particularly at older ages, by studying health care spending near the end of life. They conclude that such expenses are large and represent a substantial fraction of liquid wealth for decedents. Poterba, Venti, and Wise [?] document important correlations between poor health and asset accumulation.

Koijen, Van Nieuwerburgh, and Yogo [?] develop risk measures for health and longevity insurance and compare the risk exposure of each household in the Health and Retirement Study with the model predicted optimal risk exposure.

This paper also contributes to the literature on redistribution generated by various government programs. Although there is a lot of research about the amount of redistribution provided by Social Security and a smaller amount of research about Medicare, to the best of our knowledge this is the first paper to examine the amount of transfers provided to different income groups by Medicaid in old age. Furthermore, we are the first to assess individual's valuation of the insurance provided by Medicaid.<sup>2</sup>

## 3 Institutional background and data highlights

### 3.1 Institutional background

In the United States, there are two major public insurance programs helping the elderly with their medical expenses. The first is Medicare, a federal program that provides health insurance to almost every person over the age of 65. The second is Medicaid, a means-tested program that is run jointly by the federal and state governments.

An important characteristic of Medicaid is that it is the payer of “last resort”: Medicaid contributes only after Medicare and private insurance pay their share, and the individual spends down his assets to a “disregard” amount. Because Medicaid restricts benefits to those with assets below the disregard, it discourages saving through an additional channel not present in non-means-tested insurance, which reduces savings only by reducing risks. One area where Medicaid is particularly important is long-term care. Medicare reimburses only a limited amount of long-term care costs, and most elderly people do not have private long-term care insurance. As a result, Medicaid covers almost all nursing home costs of poor old recipients; in fact, Medicaid now assists 70 percent of nursing home residents.<sup>3</sup>

Medicaid-eligible individuals can be divided into two main groups. The first group comprises the *categorically needy*, whose income and assets fall below certain thresholds. People who receive SSI typically qualify under the categorically needy provision. The second group comprises the *medically needy*, who are individuals whose income is not particularly low, but who face such high medical expenditures that their resources become small in comparison.

The categorically needy provision thus affects the saving of people who have been poor throughout most of their lives, but has no impact on the saving of middle- and upper-income people. The medically needy provision, instead, provides insurance to

---

<sup>2</sup>Unlike Social Security, unemployment benefits, and disability insurance, Medicaid is not financed using a specific tax, but, rather, by general government revenue, and it is thus difficult to determine how redistributive the Medicaid tax rate is. For this reason, we focus on the redistribution generated by the payment of Medicaid benefits.

<sup>3</sup>Statistics from the Kaiser Foundation [?].

people with higher income and assets who are still at risk of being impoverished by expensive medical conditions.

## 3.2 The AHEAD dataset

We use data from the Assets and Health Dynamics of the Oldest Old (AHEAD) data set. The AHEAD is a survey of individuals who were non-institutionalized and aged 70 or older in 1994. It is part of the Health and Retirement Survey (HRS) conducted by the University of Michigan. We consider only single (i.e., never married, divorced, or widowed) retired individuals. A total of 3,872 singles were interviewed for the AHEAD survey in late 1993/early 1994, which we refer to as 1994. These individuals were interviewed again in 1996, 1998, 2000, 2002, 2004, and 2006. This leaves us with 3,259 individuals, of whom 592 are men and 2,667 are women. Of these 3,259 individuals, 884 are still alive in 2006. We do not use 1994 assets or medical expenses. Assets in 1994 were underreported (Rohwedder et al. [?]) and medical expenses appear to be under reported as well.

A key advantage of the AHEAD relative to other datasets is that it provides panel data on health status, including nursing home stays. We assign individuals a health status of “good” if self-reported health is excellent, very good or good and are assigned a health status of “bad” if self-reported health is fair or poor. We assign individuals to the nursing home state if they were in a nursing home at least 120 days since the last interview or if they spent at least 60 days in a nursing home before the next scheduled interview and died before that scheduled interview.

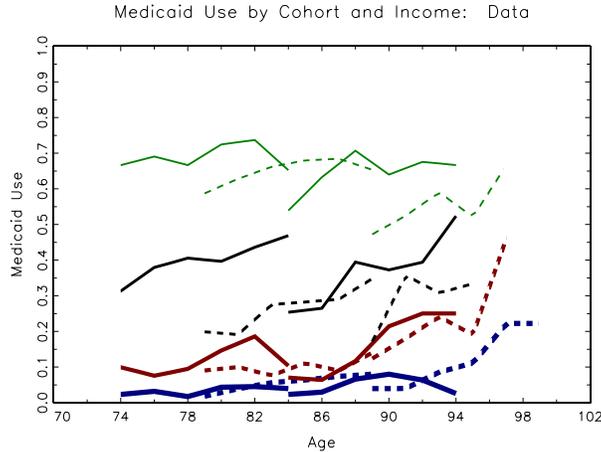

We break the data into 5 cohorts. The first cohort consists of individuals that were ages 72-76 in 1996; the second cohort contains ages 77-81; the third ages 82-86; the fourth ages 87-91; and the final cohort, for sample size reasons, contains ages 92-102. We use data for 6 different years; 1996, 1998, 2000, 2002, 2004, and 2006. We calculate summary statistics (e.g., medians), cohort-by-cohort, for surviving individuals in each calendar year—we use an unbalanced panel. We then construct life-cycle profiles by ordering the summary statistics by cohort and age at each year of observation. Moving from the left-hand-side to the right-hand-side of our graphs, we thus show data for four cohorts, with each cohort’s data starting out at the cohort’s average age in 1996. Our graphs omit profiles for the oldest cohort because sample size for this cohort is tiny.

Since we want to understand the role of income, we further stratify the data by post-retirement permanent income (PI). Hence, for each cohort our graphs usually display several horizontal lines showing, for example, average Medicaid status in each PI group in each calendar year. These lines also identify the moment conditions we use when estimating the model.

We measure post-retirement PI as the individual’s average non-asset income over all periods during which he or she is observed. Non-asset income includes the value of Social Security benefits, defined benefit pension benefits, and annuities. Because

there is a roughly monotonic relationship between lifetime earnings and the income variables that we use, our measure of post-retirement PI is also a good measure of lifetime permanent income.

### 3.3 Medicaid Reciprocity

**Figure 1:** Medicaid reciprocity rates by age, cohort, and permanent income. Thicker lines refer to higher PI groups.

AHEAD respondents are asked whether they are currently covered by Medicaid. Figure 1 plots the fraction of the sample receiving Medicaid by age, birth cohort and income quintile for all the individuals alive at each moment in time. There are four lines representing PI groupings within each cohort. We split the data into PI quintiles, but then merge the top two quintiles together because at younger ages no one in the top PI quintile is on Medicaid.

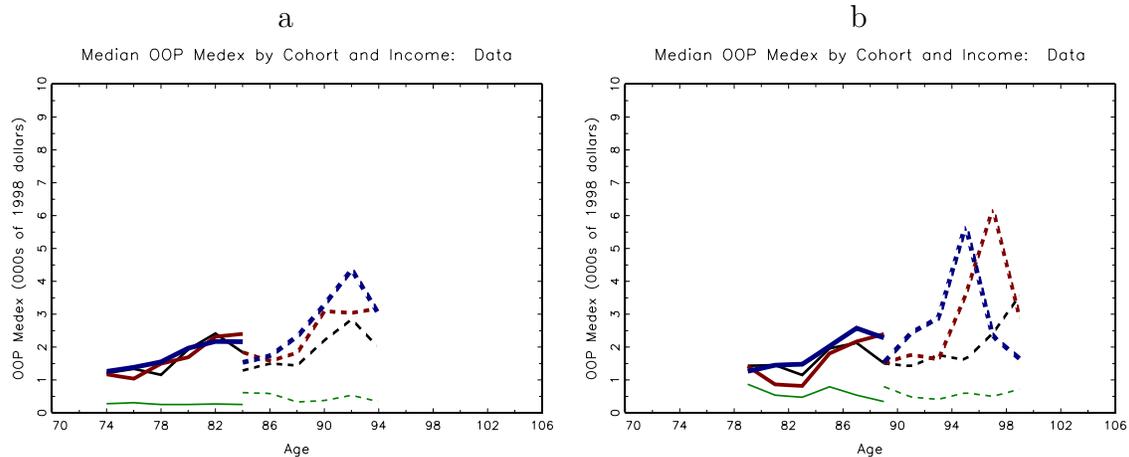

The members of the first cohort appear in our sample at an average age of 74 in 1996. We then observe them in 1998, when they are on average 76 years old, and then again every two years until 2006. The other cohorts start from older initial ages and are also followed for ten years. The graph reports the Medicaid reciprocity rate for each cohort and PI grouping for six data points over time.

Unsurprisingly, Medicaid usage is inversely related to permanent income: the top line shows the fraction of Medicaid recipients in the bottom 20% of the permanent income distribution, while the bottom line shows median assets in the top 40%. For example, the top left line shows that for the bottom PI quintile of the cohort aged 74 in 1996, about 70% of the sample receives Medicaid in 1996; this fraction stays rather stable over time. This suggests that the poorest people are qualifying for Medicaid under the categorically needy provision, where eligibility depends on income and assets, but not the amount of the medical expenses.

The Medicaid reciprocity rate tends to rise with age most quickly for people in the middle and highest PI groups. For example, Medicaid reciprocity in the oldest cohort and top two permanent income quintiles rises from about 4% at age 89 to over 20% at age 96. Even people with relatively large resources can be hit by medical shocks severe enough to exhaust their assets and qualify them for Medicaid under the medically needy provision.

### 3.4 Medical expense profiles

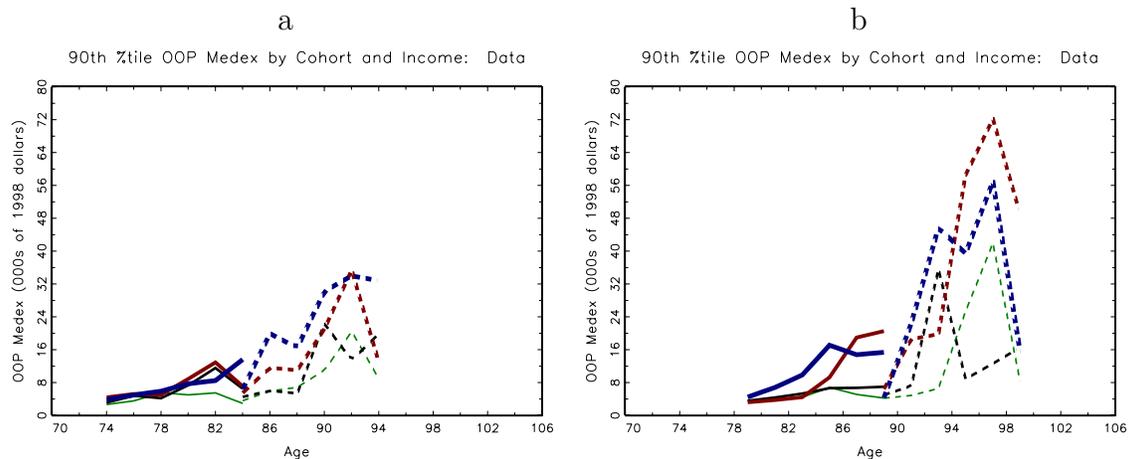

In all waves, AHEAD respondents are asked about what medical expenses they paid out of pocket. Out-of-pocket medical expenses are the sum of what the individual spends out of pocket on insurance premia, drug costs, and costs for hospital, nursing home care, doctor visits, dental visits, and outpatient care. It includes medical expenses during the last year of life. It does not include expenses covered by insurance, either public or private.

**Figure 2:** Median out-of-pocket medical expenditures by age, cohort, and permanent income.

French and Jones [?] show that the medical expense data in the AHEAD line up with the aggregate statistics. For our sample, mean medical expenses are \$3,712 with a standard deviation of \$13,429 in 1998 dollars. Although this figure is large, it is not surprising, because Medicare did not cover prescription drugs for most of the sample period, requires co-pays for services, and caps the number of reimbursed nursing home and hospital nights.

Figures 2 and 3 display the median and 90th percentile of the out-of-pocket medical expense distribution, respectively. The bottom two quintiles of permanent income are merged as there is very little variation in out-of-pocket medical expenses in the lowest quintile until very late in life: at younger ages, most of the expenses in the bottom quintile are bottom-coded at \$250. The graphs highlight the large increase

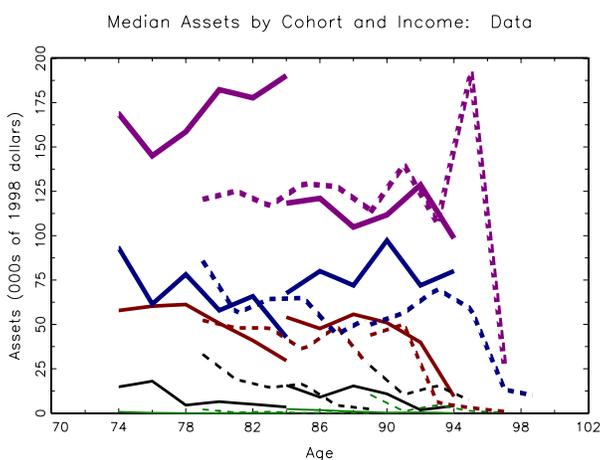

**Figure 3:** 90th percentile out-of-pocket medical expenditures by age, cohort, and permanent income.

in out-of-pocket medical expenses as people reach very advanced ages and show that this increase is especially pronounced for people in the highest PI quintiles.

### 3.5 Net worth profiles

Our measure of net worth (or assets) is the sum of all assets less mortgages and other debts. The AHEAD has information on the value of housing and real estate, autos, liquid assets (which include money market accounts, savings accounts, T-bills, etc.), IRAs, Keoghs, stocks, the value of a farm or business, mutual funds, bonds, and “other” assets.

**Figure 4:** Median assets by age, cohort, and permanent income. Thicker lines refer to higher PI groups.

Figure 4 reports median assets by cohort, age, and PI quintile. However, the fifth, bottom line is hard to distinguish from the horizontal axis because households in this PI quintile hold few assets. Unsurprisingly, assets turn out to be monotonically increasing in income, so that the bottom line shows median assets in the lowest PI quintile, while the top line shows median assets in the top quintile. For example, the top left line shows that for the top PI quintile of the cohort age 74 in 1996, median assets started at \$170,000 and then stayed rather stable over time: \$150,000 at age 76, \$160,000 at age 78, \$180,000 at ages 80 and 82, and \$190,000 at age 84.

For all PI quintiles in these cohorts, the assets of surviving individuals neither rise rapidly nor decline rapidly with age. If anything, those with high income tend to have their assets increase as they age, whereas those with low income tend to have their assets decrease. The slow rate at which the elderly deplete their wealth was a long-standing puzzle (see for example, Mirer [?]). However, as De Nardi, French, and Jones [?] show, the risk of medical spending rising with age and income goes a long way toward explaining this puzzle.

## 4 The model

We focus on single people, male or female, who have already retired. This allows us to abstract from labor supply decisions and from complications arising from changes in family size.

### 4.1 Preferences

Individuals in this model receive utility from the consumption of both non-medical and medical goods. Each period, their flow utility is given by

$$u(c_t, m_t, \mu(\cdot)) = \frac{1}{1-\nu} c_t^{1-\nu} + \mu(h_t, \zeta_t, \xi_t, t) \frac{1}{1-\omega} m_t^{1-\omega}, \quad (1)$$

where  $t$  is age,  $c_t$  is consumption of non-medical goods,  $m_t$  is total consumption of medical goods, and  $\mu(\cdot)$  is the medical needs shifter, which affects the marginal utility of consuming medical goods and services. The consumption of both goods is expressed in dollar values. The intertemporal elasticities for the two goods,  $1/\nu$  and  $1/\omega$ , can differ.

We assume that  $\mu(\cdot)$  shifts with medical needs, such as dementia, arthritis, or a broken bone. These shocks affect the utility of consuming medical goods and services, including nursing home care. Formally, we model  $\mu(\cdot)$  as a function of age, the discrete-valued health status indicator  $h_t$ , and the medical needs shocks  $\zeta_t$  and  $\xi_t$ . Individuals optimally choose how much to spend in response to these shocks.

A complementary approach is that of Grossman [?], in which medical expenses represent investments in health capital, which in turn decreases mortality (e.g., Yogo [?]) or improves health. While a couple of studies find that medical expenditures have

significant effects on health and/or survival (Card et al. [?]; Doyle [?]), most others find small effects (Brook et al. [?]; Fisher et al. [?]; Finkelstein and McKnight [?]; Khwaja [?]); see De Nardi et al. [?] for a discussion. These findings suggest that the effects of medical expenditures on the health outcomes are, at a minimum, extremely difficult to identify. Identification problems include reverse causality (sick people have higher health expenditures) and lack of insurance variation (most elderly individuals receive Medicare or Medicaid). Given that older people have already shaped their health and lifestyle, we view our assumption that their health and mortality depend on their lifetime earnings, but is exogenous to their current decisions, to be a reasonable simplification.

## 4.2 Insurance Mechanisms

We model two important types of health insurance. The first one pays a proportional share of total medical expenses and can be thought of as a combination of Medicare and private insurance. Let  $q(h_t)$  denote the individual's co-insurance (co-pay) rate, i.e., the share of medical expenses not paid by Medicare or private insurance. We allow the co-pay rate to depend on whether a person is in a nursing home ( $h_t = 1$ ) or not. Because nursing home stays are virtually uninsured by Medicare and private insurance, people residing in nursing homes face much higher co-pay rates. However, co-pay rates do not vary much across other medical conditions.

The second type of health insurance that we model is Medicaid, which is means-tested. To link Medicaid transfers to medical needs,  $\mu(h_t, \zeta_t, \xi_t, t)$ , we assume that each period Medicaid guarantees a minimum level of flow utility  $\underline{u}_i$ , which differs between categorically needy ( $i = c$ ) and medically needy ( $i = m$ ) recipients. More precisely, once the Medicaid transfer is made, an individual with the state vector  $(h_t, \zeta_t, \xi_t, t)$  can afford a consumption-medical goods pair  $(c_t, m_t)$  such that

$$\underline{u}_i = \frac{1}{1-\nu} c_t^{1-\nu} + \mu(h_t, \zeta_t, \xi_t, t) \frac{1}{1-\omega} m_t^{1-\omega}. \quad (2)$$

To implement our utility floor, for every value of the state vector, we find the expenditure level  $\underline{x}_i = c_t + m_t q(h_t)$  needed to achieve the desired current utility (equation(2)), assuming that individuals make intratemporally optimal decisions. This yields the minimum expenditure  $\underline{x}_c(\cdot)$  or  $\underline{x}_m(\cdot)$ , which correspond to the categorically and medically needy utility floors. The actual amount that Medicaid transfers,  $b_c(a_t, y_t, h_t, \zeta_t, \xi_t, t)$  or  $b_m(a_t, y_t, h_t, \zeta_t, \xi_t, t)$ , is then given by  $\underline{x}_c(\cdot)$  or  $\underline{x}_m(\cdot)$  less the individual's total financial resources (assets,  $a_t$ , and non-asset income,  $y_t$ ).

## 4.3 Uncertainty and Non-Asset Income

The individual faces several sources of risk, which we treat as exogenous: health status risk, survival risk, and medical needs risk. At the beginning of each period,

the individual's health status, and medical needs shocks are realized and need-based transfers are given. The individual then chooses consumption, medical expenditure, and saves. Finally, the survival shock hits.

We parameterize the preference shifter for medical goods and services (the needs shock) as

$$\log(\mu(\cdot)) = \alpha_0 + \alpha_1 t + \alpha_2 t^2 + \alpha_3 t^3 + \alpha_4 h_t + \alpha_5 h_t \times t \quad (3)$$

$$+ \sigma(h, t) \times \psi_t, \quad (4)$$

$$\sigma(h, t)^2 = \beta_0 + \beta_1 t + \beta_2 t^2 + \beta_4 h_t + \beta_5 h_t \times t \quad (5)$$

$$\psi_t = \zeta_t + \xi_t, \quad \xi_t \sim N(0, \sigma_\xi^2), \quad (6)$$

$$\zeta_t = \rho_m \zeta_{t-1} + \epsilon_t, \quad \epsilon_t \sim N(0, \sigma_\epsilon^2), \quad (7)$$

$$\sigma_\xi^2 + \frac{\sigma_\epsilon^2}{1 - \rho_m^2} \equiv 1, \quad (8)$$

where  $\xi_t$  and  $\epsilon_t$  are serially and mutually independent. We thus allow the need for medical services to have temporary ( $\xi_t$ ) and persistent ( $\zeta_t$ ) shocks. It is worth stressing that we not allow any component of  $\mu(\cdot)$  to depend on permanent income; income affects medical expenditures solely through the budget constraint.

Health status can take on three values: good (3), bad (2), and in a nursing home (1). We allow the transition probabilities for health to depend on previous health, sex ( $g$ ), permanent income ( $I$ ), and age. The elements of the health status transition matrix are

$$\pi_{j,k,g,I,t} = \Pr(h_{t+1} = k | h_t = j, g, I, t), \quad j, k \in \{1, 2, 3\}. \quad (9)$$

Mortality also depends on health, sex, permanent income and age. Let  $s_{g,h,I,t}$  denote the probability that an individual of sex  $g$  is alive at age  $t + 1$ , conditional on being alive at age  $t$ , having time- $t$  health status  $h$ , and enjoying permanent income  $I$ .

Non-asset income  $y_t$ , is a deterministic function of sex, permanent income, and age:

$$y_t = y(g, I, t). \quad (10)$$

## 4.4 The Individual's Problem

Consider a single person seeking to maximize his or her expected lifetime utility at age  $t$ ,  $t = t_{r+1}, \dots, T$ , where  $t_r$  is the retirement age.

To be categorically needy this person's income and assets need to be below  $\underline{Y}$  and  $A_d$ , respectively. Besides being the maximum amount of income (excluding disregards) that one can have and still qualify for SSI/Medicaid,  $\underline{Y}$  is also the maximum SSI benefit that one can receive.

Note that Medicaid and SSI apply to income *gross* of taxes. Let  $a_t$  denote assets and  $r$  the real interest rate. The SSI benefit equals  $\underline{Y} - \max\{y_t + r a_t - y_d, 0\}$ , where  $y_d$  is the income disregard.

If a person is categorically needy and applies for SSI and Medicaid, he receives the SSI transfer and Medicaid goods and services as dictated by his medical needs shock and utility floor. The combined SSI/Medicaid transfer for the categorically needy is thus given by:

$$b_c(a_t, y_t, \mu(\cdot)) = \underline{Y} - \max\{y_t + ra_t - y_d, 0\} + \max\{0, \underline{x}_c - \max\{a_t + \underline{Y} - A_d, 0\}\}, \quad (11)$$

Under this formulation, agents with assets in excess of the disregard  $A_d$  can spend down their wealth and qualify for Medicaid.

If the person's total income is above  $\underline{Y}$  and or assets are above and  $A_d$ , she is not eligible for SSI. If the person applies for Medicaid, transfers are given by

$$b_m(a_t, y_t, \mu(\cdot)) = \max\{0, \underline{x}_m(\cdot) - \max\{a_t + ra_t + y_t - A_d, 0\}\}, \quad (12)$$

where we assume that the asset disregard  $A_d$  is the same as under the categorically needy pathway.

Each period eligible individuals choose whether to receive Medicaid or not. We will use the indicator function  $I_M$  to denote this choice, with  $I_M = 1$  if the person applies for Medicaid and  $I_M = 0$  if the person does not apply.

Using  $\beta$  to denote the discount factor, we can then write the individual's value function as:

$$V_t(a_t, g, h_t, I, \zeta_t, \xi_t) = \max_{c_t, m_t, a_{t+1}, I_M} \left\{ u(c_t, m_t, \mu(\cdot)) + \beta s_{g,h,I,t} E_t \left( V_{t+1}(a_{t+1}, g, h_{t+1}, I, \zeta_{t+1}, \xi_{t+1}) \right) \right\}, \quad (13)$$

subject to the law of motion for the shocks and the following constraints. If  $I_M = 0$ , i.e., the person does not apply for SSI and Medicaid,

$$a_{t+1} = a_t + y_n(ra_t + y_t) - c_t - q(h_t)m_t \geq 0, \quad (14)$$

If  $I_M = 1$ , i.e., the person applies for SSI and Medicaid, we have

$$a_{t+1} = b_i(\cdot) + a_t + y_n(ra_t + y_t) - c_t - q(h_t)m_t \geq 0, \quad (15)$$

$$a_{t+1} \leq \min\{A_d, a_t\}, \quad (16)$$

where  $b_i(\cdot) = b_c(\cdot)$  if  $Y_t \leq \underline{Y}$  and  $b_i(\cdot) = b_m(\cdot)$  otherwise.

To express the dynamic programming problem as a function of  $c_t$  only, we can derive  $m_t$  as a function of  $c_t$  by using the optimality condition implied by the intratemporal allocation decision. Suppose that at time  $t$  the individual decides to spend the total  $x_t$  on consumption and out-of-pocket payments for medical goods. The optimal intratemporal allocation then solves:

$$\mathcal{L} = \frac{1}{1-\nu} c_t^{1-\nu} + \mu(\cdot) \frac{1}{1-\omega} m_t^{1-\omega} + \lambda_t (x_t - m_t q(h_t) - c_t),$$

where  $\lambda_t$  is the multiplier on the intratemporal budget constraint. The first-order conditions for this problem reduce to

$$m_t = \left( \frac{\mu(\cdot)}{q(h_t)} \right)^{1/\omega} c_t^{\nu/\omega}. \quad (17)$$

This expression can be used to eliminate  $m_t$  from the dynamic programming problem in equation (13).

## 5 Estimation procedure

We adopt a two-step strategy to estimate the model. In the first step we estimate or calibrate those parameters that can be cleanly identified outside our model. For example, we estimate mortality rates from raw demographic data. In the second step we estimate the rest of the model’s parameters ( $\nu, \omega, \beta, \underline{u}_c, \underline{u}_m$ , and the parameters of  $\ln \mu(\cdot)$ ) with the method of simulated moments (MSM), taking as given the parameters that were estimated in the first step. In particular, we find the parameter values that allow simulated life-cycle decision profiles to “best match” (as measured by a GMM criterion function) the profiles from the data. The moment conditions that comprise our estimator are:

1. To better evaluate the effects of Medicaid insurance, we match the fraction of people on Medicaid by PI quintile, cohort and age (with the top two permanent income quintiles merged together).
2. Because the effects of Medicaid depend directly on an individual’s asset holdings, we match median asset holdings by birth-year cohort, permanent income, and calendar year. We sort individuals into PI quintiles, and the 5 birth-year cohorts described in section 3. We then compare data and model-generated cell medians in 5 different years (1998, 2000, 2002, 2004, and 2006).<sup>4</sup>
3. We match the median and 90th percentile of the out-of-pocket medical expense distribution in each year-cohort-PI cell (the bottom two quintiles are merged). Because the AHEAD’s medical expense data are reported net of any Medicaid payments, we deduct government transfers from the model-generated expenses before making any comparisons.
4. To capture the dynamics of medical expenses, we match the first and second autocorrelations for medical expenses in each year-cohort-PI cell.

---

<sup>4</sup>Simulated agents are endowed with asset levels drawn from the 1996 data distribution. Cells with less than 10 observations are excluded from the moment conditions.

The mechanics of our MSM approach are as follows. We compute life-cycle histories for a large number of artificial individuals. Each of these individuals is endowed with a value of the state vector  $(t, a_t, g, h_t, I)$  drawn from the data distribution for 1996, and each is assigned the entire health and mortality history realized by the person in the AHEAD data with the same initial conditions. The simulated medical needs shocks  $\zeta$  and  $\xi$  are Monte Carlo draws from discretized versions of our estimated shock processes.

We discretize the asset grid and, using value function iteration, we solve the model numerically. This yields a set of decision rules, which, in combination with the simulated endowments and shocks, allows us to simulate each individual’s net worth, medical expenditures, health, and mortality. We then compute asset, medical expense and Medicaid profiles from the artificial histories in the same way as we compute them from the real data. We use these profiles to construct moment conditions, and evaluate the match using our GMM criterion. We search over the parameter space for the values that minimize the criterion. Appendix A contains a detailed description of our moment conditions, the weighting matrix in our GMM criterion function, and the asymptotic distribution of our parameter estimates.

## 6 First-step estimation results

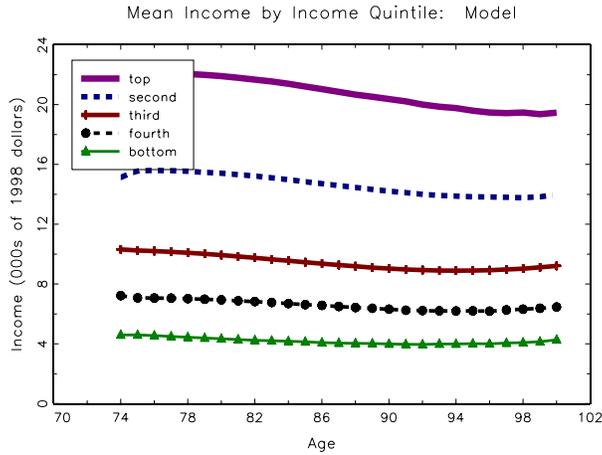

In this section, we briefly discuss the life cycle profiles of the stochastic variables used in our dynamic programming model. The process for income is estimated using the procedure in De Nardi et al. [?], and is described in more detail there. The procedure for estimating demographic transition probabilities and and co-pay rates are new.

### 6.1 Income profiles

We model non-asset income as a function of age, sex, health status, and the individual’s PI ranking. Figure 5 presents average income profiles, conditional on permanent income quintile, computed by simulating our model. In this simulation we do not let people die, and we simulate each person’s financial and medical history up through the oldest surviving age allowed in the model. Since we rule out attrition, this picture shows how income evolves over time for the same sample of elderly people. Figure 5 shows that average annual income ranges from about \$4,000 per year in the bottom PI quintile to about \$20,000 in the top quintile; median wealth holdings for the two groups are zero and just under \$200,000, respectively.

### 6.2 Mortality and health status

We estimate health transitions and mortality rates simultaneously by fitting the transitions observed in the HRS to a multinomial logit model. We allow the transition

**Figure 5:** Average income, by permanent income quintile.

probabilities to depend on age, sex, current health status, and permanent income. We estimate annual transition rates: combining annual transition probabilities in consecutive years yields two-year transition rates we can fit to the AHEAD data. Appendix B gives details on the procedure.

Using the estimated transition probabilities, we simulate demographic histories, beginning at age 70, for different gender-PI-health combinations. Table 1 shows life expectancies. We find that rich people, women, and healthy people live much longer than their poor, male, and sick counterparts. For example, a male at the 10th permanent income percentile in a nursing home expects to live only 3.5 more years, while a female at the 90th percentile in good health expects to live 16.1 more years.

Income Percentile	Nursing Home	<u>Males</u>		<u>Females</u>			All <sup>†</sup>
		Bad Health	Good Health	Nursing Home	Bad Health	Good Health	
10	3.53	5.86	7.22	6.02	9.99	11.97	10.38
30	3.61	6.40	8.14	6.41	10.92	13.04	11.36
50	3.77	7.05	9.11	6.85	11.94	14.18	12.36
70	3.98	7.81	10.10	7.38	12.96	15.20	13.40
90	4.26	8.61	11.01	8.05	13.97	16.14	14.31
By gender: <sup>‡</sup>							
Men							9.41
Women							13.54
By health status: <sup>◊</sup>							
Bad Health							10.56
Good Health							13.93

Notes: Life expectancies calculated through simulations using estimated health transition and survivor functions. <sup>†</sup> Using gender and health distributions for entire population; <sup>‡</sup> Using health and permanent income distributions for each gender; <sup>◊</sup> Using gender and permanent income distributions for each health status group.

**Table 1:** Life expectancy in years, conditional on reaching age 70.

Another important saving determinant is the risk of requiring nursing home care. Table 2 shows the probability at age 70 of ever entering a nursing home. The calculations show that 30.1% of women will ultimately enter a nursing home, as opposed to 17.9% for men. These numbers are lower than those from the Robinson model described in Brown and Finkelstein [?] which show 27% of 65-year-old men and 44% of 65-year-old women require nursing home care. One reason we find lower numbers is that the Robinson model is based on older data, and nursing home utilization has declined in recent years (Alecxih [?]).

Income Percentile	<u>Males</u>		<u>Females</u>		All <sup>†</sup>
	Bad Health	Good Health	Bad Health	Good Health	
10	15.9	17.6	26.6	28.8	26.0
30	15.8	17.8	27.3	29.6	26.4
50	15.7	18.1	27.8	30.6	27.1
70	16.1	19.0	29.0	32.0	27.9
90	16.4	18.8	30.2	33.2	29.4
By gender: <sup>‡</sup>					
Men					17.9
Women					30.1
By health status: <sup>◊</sup>					
Bad Health					25.4
Good Health					29.0

Notes: Entry probabilities calculated through simulations using estimated health transition and survivor functions; <sup>†</sup> Using gender and health distributions for entire population; <sup>‡</sup> Using health and permanent income distributions for each gender; <sup>◊</sup> Using gender and permanent income distributions for each health status group.

**Table 2:** Probability of ever entering a nursing home, people alive at age 70.

### 6.3 Co-pay rates

The co-pay rate  $q_t = q(h_t)$  is the share of total billable medical spending not paid by Medicare or private insurers. Thus, it is the share paid out of pockets or by Medicaid. We allow it to differ depending on whether the person is in a nursing home or not:  $q_t = q(h_t)$ .

There are two problems with inferring co-pay rates using out of pocket medical expenses and total billable medical expenses from the AHEAD data. First, total medical expense information are largely imputed in this data set. Second, since we explicitly model Medicaid, we have to make sure that Medicaid payments are included in our measure of total medical expenses. Unfortunately, the AHEAD data provide no information on Medicaid payments.

For these reasons, to estimate co-pay rates for people not in a nursing home, we use data from the 2005 panel of the Medical Expense Panel Survey (MEPS), which is a representative sample of the non-institutionalized population. MEPS provides high

quality information on total billable medical expenses as well as the payor of those expenses, including Medicaid. It does so by collecting medical expenses data from health care providers as well as from individuals.

The co-pay rate for people not in a nursing home averages 29% in MEPS and does not vary much with demographics. We compute these numbers by applying the same data filters to MEPS that we used for the AHEAD data. Next, we estimate  $q(h_t)$  by taking the ratio of mean out of pocket spending plus Medicaid payments to mean total medical expenses.

To estimate the co-pay rate for those in nursing homes we use data from the 2006 Medicare Current Beneficiary Survey (MCBS), which is a representative sample of Medicare enrollees aged 65+. These data reveal that the co-pay rate for those in nursing homes is 92%. For every dollar spent on nursing homes, 47 cents come from Medicaid and 45 cents are from out of pocket, with only 8 cents coming from Medicare or other sources.

## 7 Second step results and model fit

Our estimates are still preliminary.

### 7.1 Parameter values

Our estimate of  $\beta$ , the discount factor is 1.13. This number has to be multiplied by the survival probability to obtain the effective discount factor. Given the advanced age of people in our sample, the survival probability is low (under 50% for the older people). This implies that our effective estimated discount rate is also low for the households in our sample.

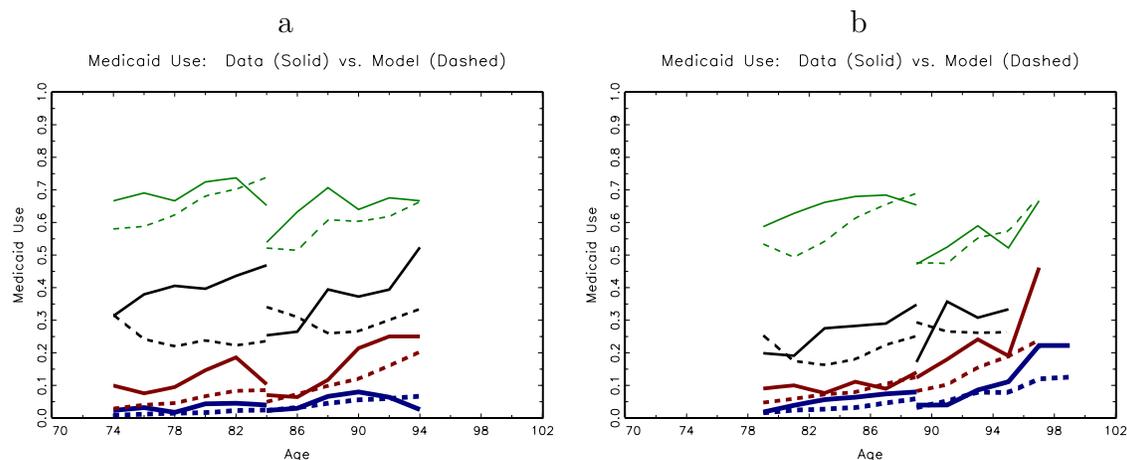

The estimate of  $\nu$ , the coefficient of relative risk aversion for “regular” consumption, is 2.9, while the estimate of  $\omega$ , the coefficient of relative risk aversion for medical goods, is 3.4; the demand for medical goods is less elastic than the demand for consumption.

The utility floors correspond to the utility levels a person gets when the medical needs shifter  $\mu$  equals 0 (no medical needs) and the person consumes \$1,500 for the categorically needy and \$4,300 for the medically needy. It should be noted that the medically needy are also guaranteed a minimum income level of \$6,000, so that their total consumption when healthy is \$6,000 a year. However, when there are large medical needs, transfers are determined by the utility floor, and the medically needy are more insured than the categorically needy.

We also estimate the coefficients for the mean of the logged medical needs shifter  $\mu(h_t, \psi_t, t)$ , the volatility scaler  $\sigma(h_t, t)$  and the process for the shocks  $\zeta_t$  and  $\xi_t$ . As we show in the graphs that follow, the estimates for these parameters (available from the authors on request) imply that the demand for medical services rises rapidly with age.

We now turn to discussing how well the model fits the some key aspects of the data and also look at some additional model implications.

## 7.2 Medicaid reciprocity

**Figure 6:** Medicaid reciprocity by cohort and PI quintile: data (solid lines) and model (dashed lines).

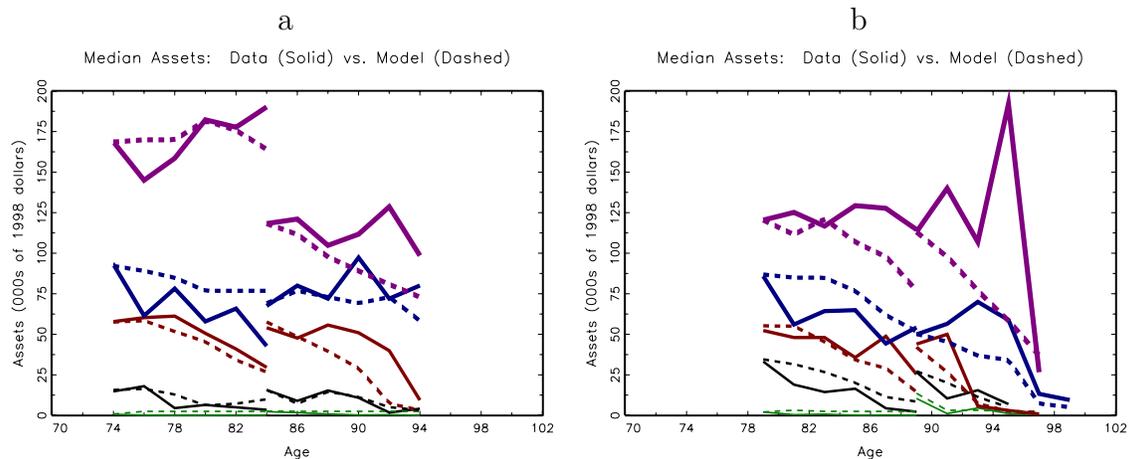

Figure 6 compares the Medicaid reciprocity profiles generated by the model (dashed line) to those in the data (solid line) for the members of two birth-year cohorts. In panel a, the lines at the far left of the graph are for the youngest cohort, whose members in 1996 were aged 72-76, with an average age of 74. The second set of lines are for the cohort aged 82-86 in 1996. Panel b displays the two other cohorts, starting respectively at age 79 and 89. The graphs show that the model matches well both the usage levels and their rise by age and permanent income.

## 7.3 Net worth profiles

Figure 7 plots median net worth by age, cohort, and permanent income. Here too the model does well, matching the observation that the savings patterns differ by permanent income and that higher PI people don't run down their assets until well past age 90.

## 7.4 Medical expenses

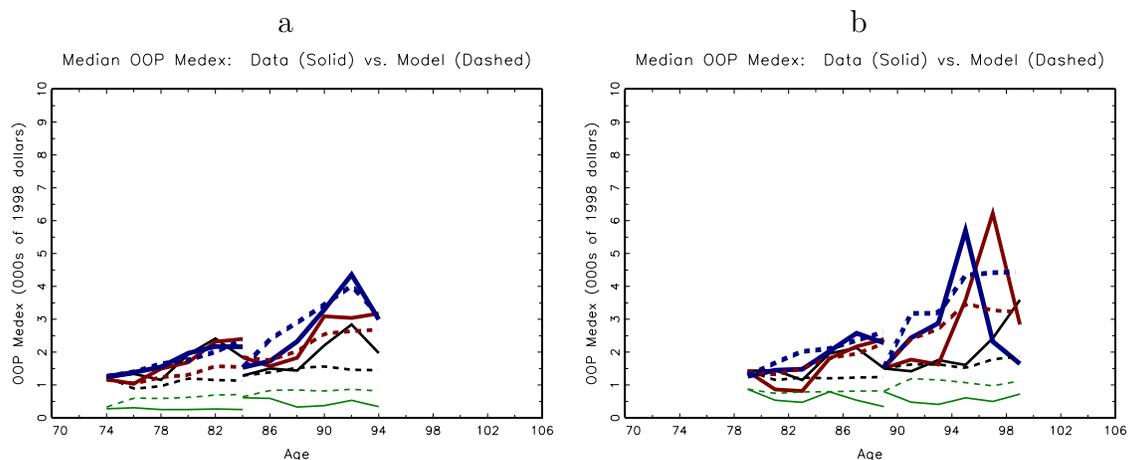

Figure 8 displays median out-of-pocket medical expenses (that is, net of Medicaid payments and private and public insurance co-pays) paid by people in the model and in the data. Permanent income has a large effect on out-of-pocket medical expenses, especially at older ages. Median medical expenses are less than \$2,000 a year at

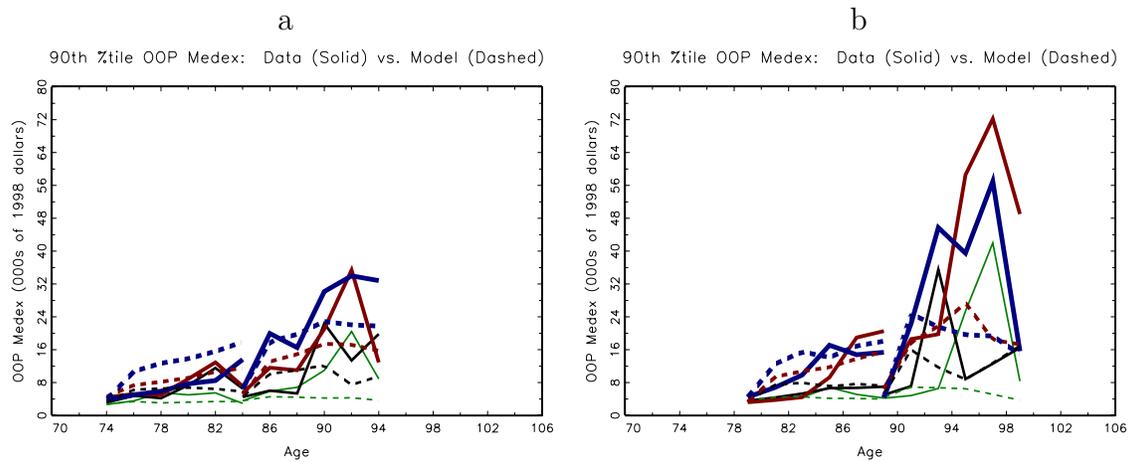

**Figure 7:** Median net worth by cohort and PI quintile: data (solid lines) and model (dashed lines).

age 75. By age 100, they stay flat for those in the bottom quintile of the income distribution but rise to over \$6,000 for those at the top of the income distribution. The model does a reasonable job of matching the key patterns in the data.

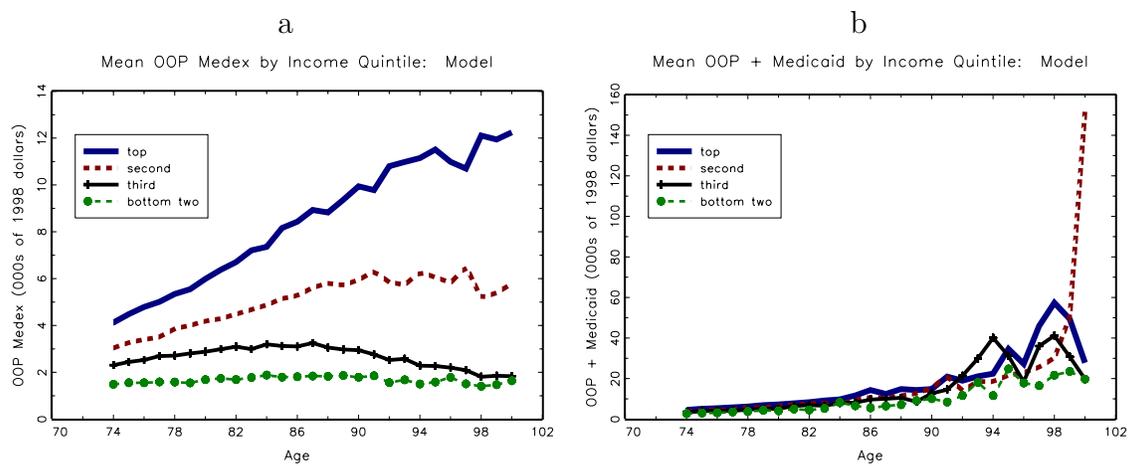

Figure 9 compares the 90th percentile of out-of-pocket medical expenses generated by the model to those found in the data and thus provides some better idea of the tail risk by age and permanent income. Here the model reproduces medical expenses of \$5,000 or less at age 74, staying flat over time for the lower PI people, but understates the medical of the high PI people in their late nineties.

**Figure 8:** Out-of-pocket medical expenses by cohort and PI quintile: data (solid lines) and model (dashed lines).

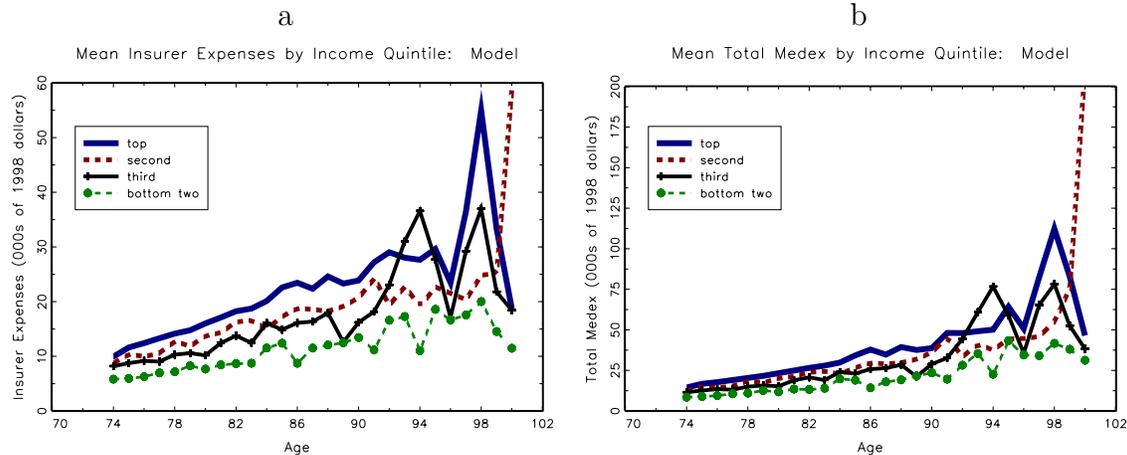

**Figure 9:** Ninetieth percentile of out-of-pocket medical expenses by cohort and PI quintile: data (solid lines) and model (dashed lines).

**Figure 10:** Average medical expenses by age and permanent income. Panel a: paid by Medicaid. Panel b: paid by Medicaid or out-of-pocket.

Figure 10 presents profiles that arise when the youngest cohort is simulated from ages 74 to (potentially) 100. Panel a shows average out-of-pocket medical expenses, which follow a pattern similar to that in Figures 8 and 9. Panel b of Figure 10 shows the sum of medical expenses paid out-of-pocket and the expenses paid by Medicaid, the latter measured as the increase in  $q(h_t)m_t$  generated by government transfers. These sums also increase rapidly with age, going from around \$3,500 at age 74 to \$40,000 at age 99. Medicaid allows poorer people to consume proportionally much more medical goods and services than they pay for. As a result, the expense sum shown in panel b rises more slowly with income than the out-of-pocket expenditures shown in panel a.

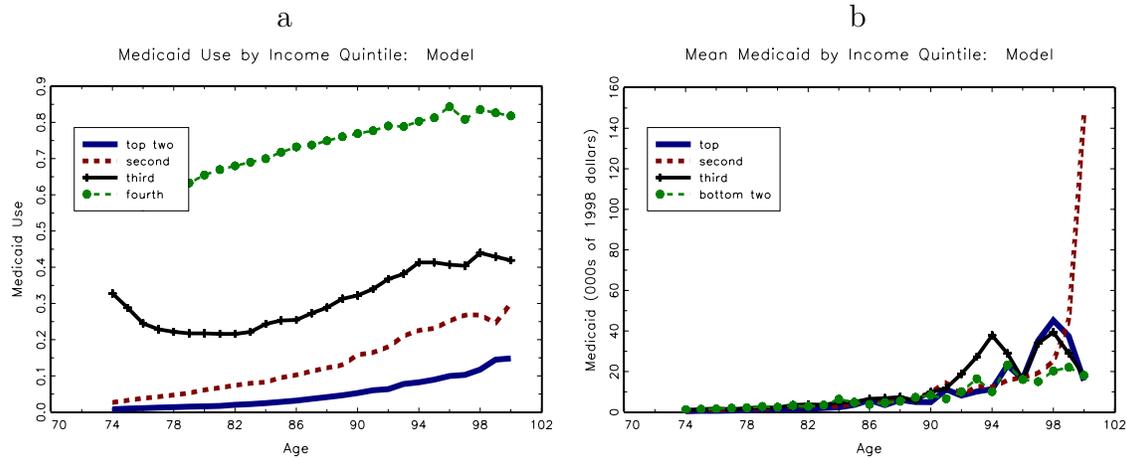

**Figure 11:** Average medical expenses by age and permanent income. Panel a: paid by insurers. Panel b: total.

Panel a of Figure 11 displays average medical expenses covered by private and public insurers. These payments are very large and also increase by age and permanent income, reaching over \$50,000 for the oldest members of the top permanent income quintile. The oldest in the poorest permanent income quintile, however, also benefit from these payments, which reach around \$20,000 at age 98. Panel b of Figure 11 displays total medical expenses, which in this case also coincide with total consumption of medical goods and services. Comparing the two panels makes it clear that most elderly individuals consume far more medical care than they pay out-of-pocket. The increase in total medical expenses after retirement is very large, going from around \$10,000 at age 74 to \$70 thousand at age 100.

## 7.5 Utility floor, preference shocks, and implied insurance system

Through the interaction of the utility floor and medical needs shocks, the model has interesting implications on the insurance provided by means-tested programs.

Figure 12 describes the transfers generated by the model. Panel a of this figure shows the fraction of individuals receiving transfers, while panel b shows average transfers, taken across both recipients and non-recipients. Panel a shows that people in the bottom two permanent income quintiles receive Medicaid at fairly high rates throughout their retirement. Most of these people qualify through the categorically needy pathway. People in the top income quintiles, in contrast, use Medicaid much more heavily at older ages, when large medical expenditures make them eligible through the medically needy pathway.

**Figure 12:** Medicaid. Panel a: fraction receiving Medicaid. Panel b: average Medicaid transfers.

Panel b of Figure 12 shows average Medicaid transfers. While low-income people are much more likely to qualify for Medicaid, the categorically needy provision allows them to qualify with small medical needs. The medically needy provision allows high-income people to qualify only when their medical expenses are high as well. Although the poor on average receive more Medicaid benefits than the rich at younger ages, at very old ages the two groups receive similar benefits.

## 8 Medicaid Redistribution

In this section we perform some preliminary experiments to assess the amount of redistribution that Medicaid provides. To do this we simulate our estimated model, including Medicaid payments. Each simulated individual receives a value of the state vector  $(t, a_t, g, h_t, I)$  drawn from the data distribution of 72- to 76-year-olds in 1996. He or she then receives a series of health, medical expense, and mortality shocks consistent with the stochastic processes described in the model section, and is tracked to age 100. We calculate the present discounted value of Medicaid payments for each simulated individual.

The left-hand column of Table 3 reports the average present discounted value of payments conditional on income quintile, gender and health status at age 74. Surprisingly, those in the third income quintile receive the largest transfers. Although the poor are more likely to be receiving Medicaid, the poor tend to die before they develop the most costly health conditions. Women benefit more than men from Medicaid, both because they live longer and because they tend to be poorer. Finally, those in good health at age 74 receive more benefits than those in bad health at 74 because they tend to live long enough to require costly procedures and long nursing home stays.

Income Quintile	Present Discounted Value	Annuity Value
Bottom	22,200	2,820
Fourth	29,300	3,380
Third	37,300	3,950
Second	33,000	3,300
Top	25,500	2,530
Men	15,500	2,160
Women	32,400	3,290
In Good Health	29,800	2,910
In Bad Health	29,300	3,560

**Table 3:** Medicaid Payments at age 74.

The right-hand column of table 3 reports the annuity value of the same Medicaid payments. We calculate the annuity value as the average present discounted sum divided by the average lifespan (adjusted for discounting). The annuity value calculations show that an important part of the reason for why rich people benefit from Medicaid is the mechanical relationship between income and lifespan. Rich people have more years to collect benefits. Another part of the explanation, however, is that the older ages at which rich people are more likely to be alive are the ages when the most expensive medical conditions hit, hence average transfers are an increasing function of one's lifespan.

The AHEAD data does not have direct measures of Medicaid payments. We must infer these payments indirectly using the model. In order to verify that these model predictions are accurate, we are in the process of acquiring MCBS data. Preliminary analysis from the MCBS suggests that we might be overstating Medicaid payments to the richest, but that these payments are considerable for this group. For example,

average payments those in the bottom two quintiles of the income distribution are \$3,628 per year, whereas those in the top three quintiles are receive on average \$1,096 per year. But these estimates are still extremely preliminary and don't correspond exactly to the type of life-long computations that we perform in the model.

Income Quintile	Present Discounted Value	Annuity Value
Bottom	91,600	11,630
Fourth	123,500	14,270
Third	176,400	18,680
Second	213,800	21,360
Top	258,400	25,640
Men	147,300	20,570
Women	193,400	19,600
In Good Health	207,300	20,230
In Bad Health	154,900	18,820

**Table 4:** Consumption of medical goods and services at age 74.

Table 4 confirms that the rich do in fact consume more medical services than the poor: people in the top PI quintile spend over twice as much per year on medical goods as people at the bottom. While this difference in part reflects wealth effects, it also illustrates the way in which medical needs rise with age. Table 5 show that out-of-pocket medical expenses rise even more quickly with income. Although Medicaid delivers fairly similar benefits across the income distribution in absolute terms, it pays a much larger fraction of poor people's expenses.

Finally, Table 6 shows that non-medical consumption rises more quickly in income than medical spending. Given that the curvature parameter for medical expenditures  $\omega$  is larger than the curvature parameter for non-medical consumption  $\nu$ , this is not surprising.

## 9 Conclusions and extensions

To come ...

Bottom	11,700	1,480
Fourth	15,800	1,820
Third	26,000	2,760

In Bad Health	92,000	11,170

**Table 6:** Consumption at age 74.

## Appendix A: Moment conditions and asymptotic distribution of parameter estimates

Recall that we estimate the parameters of our model in the two steps. In the first step, we estimate the vector  $\chi$ , the set of parameters than can be estimated with explicitly using our model. In the second step, we use the method of simulated moments (MSM) to estimate the remaining parameters, which are contained in the  $M \times 1$  vector  $\Delta$ . The elements of  $\Delta$  are  $\nu$ ,  $\omega$ ,  $\beta$ ,  $\underline{c}$ ,  $\theta$ ,  $k$ , and the parameters of  $\ln \mu(\cdot)$ . Our estimate,  $\hat{\Delta}$ , of the “true” parameter vector  $\Delta_0$  is the value of  $\Delta$  that minimizes the (weighted) distance between the life cycle profiles found in the data and the simulated profiles generated by the model.

For each calendar year  $t \in \{t_0, \dots, t_T\} = \{1996, 1998, 2000, 2002, 2004, 2006\}$ , we match median assets for  $Q_A = 5$  permanent income quintiles in  $P = 5$  birth year cohorts.<sup>5</sup> The 1996 (period- $t_0$ ) distribution of simulated assets, however, is bootstrapped from the 1996 data distribution, and thus we match assets to the data for 1998, ..., 2006. In addition, we require each cohort-income-age cell have at least 10 observations to be included in the GMM criterion.

Suppose that individual  $i$  belongs to birth cohort  $p$  and his permanent income level falls in the  $q$ th permanent income quintile. Let  $a_{pqt}(\Delta, \chi)$  denote the model-predicted median asset level for individuals in individual  $i$ 's group at time  $t$ , where  $\chi$  includes all parameters estimated in the first stage (including the permanent income boundaries). Assuming that observed assets have a continuous conditional density,  $a_{pqt}$  will satisfy

$$\Pr(a_{it} \leq a_{pqt}(\Delta_0, \chi_0) | p, q, t, \text{individual } i \text{ observed at } t) = 1/2.$$

The preceding equation can be rewritten as a moment condition (Manski [?], Powell [?] and Buchinsky [?]). In particular, applying the indicator function produces

$$E(1\{a_{it} \leq a_{pqt}(\Delta_0, \chi_0)\} - 1/2 | p, q, t, \text{individual } i \text{ observed at } t) = 0. \quad (18)$$

Letting  $\mathcal{I}_q$  denote the values contained in the  $q$ th permanent income quintile, we can convert this conditional moment equation into an unconditional one (e.g., Chamberlain [?]):

$$\begin{aligned} E\left([1\{a_{it} \leq a_{pqt}(\Delta_0, \chi_0)\} - 1/2] \times 1\{p_i = p\} \times 1\{I_i \in \mathcal{I}_q\} \right. \\ \left. \times 1\{\text{individual } i \text{ observed at } t\} \mid t\right) = 0 \end{aligned} \quad (19)$$

for  $p \in \{1, 2, \dots, P\}$ ,  $q \in \{1, 2, \dots, Q_A\}$ ,  $t \in \{t_1, t_2, \dots, t_T\}$ .

---

<sup>5</sup>Because we do not allow for macro shocks, in any given cohort  $t$  is used only to identify the individual's age.

We also include several moment conditions relating to medical expenses. To use these moment conditions, we first simulate medical expenses at an annual frequency, and then take two-year averages to produce a measure of medical expenses comparable to the ones contained in the AHEAD.

As with assets, we divide individuals into 5 cohorts and match data from 5 waves covering the period 1998-2006. The moment conditions for medical expenses are split by permanent income as well. However, we combine the bottom two income quintiles, as there is very little variation in out-of-pocket medical expenses in the bottom quintile until very late in life;  $Q_M = 4$ .

We require the model to match the median out-of-pocket medical expenditures in each cohort-income-age cell. Let  $m_{pqt}^{50}(\Delta, \chi)$  denote the model-predicted 50th percentile for individuals in cohort  $p$  and permanent income group  $q$  at time (age)  $t$ . Proceeding as before, we have the following moment condition:

$$E\left([1\{m_{it} \leq m_{pqt}^{50}(\Delta_0, \chi_0)\} - 0.5] \times 1\{p_i = p\} \times 1\{I_i \in \mathcal{I}_q\} \times 1\{\text{individual } i \text{ observed at } t\} \mid t\right) = 0 \quad (20)$$

for  $p \in \{1, 2, \dots, P\}$ ,  $q \in \{1, 2, \dots, Q_M\}$ ,  $t \in \{t_1, t_2, \dots, t_T\}$ .

To fit the upper tail of the medical expense distribution, we require the model to match the 90th percentile of out-of-pocket medical expenditures in each cohort-income-age cell. Letting  $m_{pqt}^{90}(\Delta, \chi)$  denote the model-predicted 90th percentile, we have the following moment condition:

$$E\left([1\{m_{it} \leq m_{pqt}^{90}(\Delta_0, \chi_0)\} - 0.9] \times 1\{p_i = p\} \times 1\{I_i \in \mathcal{I}_q\} \times 1\{\text{individual } i \text{ observed at } t\} \mid t\right) = 0 \quad (21)$$

for  $p \in \{1, 2, \dots, P\}$ ,  $q \in \{1, 2, \dots, Q_M\}$ ,  $t \in \{t_1, t_2, \dots, t_T\}$ .

To pin down the autocorrelation coefficient for  $\zeta$  ( $\rho_m$ ), and its contribution to the total variance  $\zeta + \xi$ , we require the model to match the first and second autocorrelations of logged medical expenses. Define the residual  $R_{it}$  as

$$R_{it} = \ln(m_{it}) - \overline{\ln m_{pqt}},$$

$$\overline{\ln m_{pqt}} = E(\ln(m_{it}) \mid p_i = p, q_i = q, t)$$

and define the standard deviation  $\sigma_{pqt}$  as

$$\sigma_{pqt} = \sqrt{E(R_{it}^2 \mid p_i = p, q_i = q, t)}.$$

Both  $\overline{\ln m_{pqt}}$  and  $\sigma_{pqt}$  can be estimated non-parametrically as elements of  $\chi$ . Using these quantities, the autocorrelation coefficient  $AC_{pqtj}$  is:

$$AC_{pqtj} = E\left(\frac{R_{it}R_{i,t-j}}{\sigma_{pqt}\sigma_{pq,t-j}} \mid p_i = p, q_i = q\right).$$

Let  $AC_{pqtj}(\Delta, \chi)$  be the  $j$ th autocorrelation coefficient implied by the model, calculated using model values of  $\overline{\ln m_{pqt}}$  and  $\sigma_{pqt}$ . The resulting moment condition for the first autocorrelation is

$$E \left( \left[ \frac{R_{it}R_{i,t-1}}{\sigma_{pqt} \sigma_{pq,t-1}} - AC_{pqt1}(\Delta_0, \chi_0) \right] \times 1\{p_i = p\} \times 1\{I_i \in \mathcal{I}_q\} \right. \\ \left. \times 1\{\text{individual } i \text{ observed at } t \ \& \ t - 1\} \mid t \right) = 0. \quad (22)$$

The corresponding moment condition for the second autocorrelation is

$$E \left( \left[ \frac{R_{it}R_{i,t-2}}{\sigma_{pqt} \sigma_{pq,t-2}} - AC_{pqt2}(\Delta_0, \chi_0) \right] \times 1\{p_i = p\} \times 1\{I_i \in \mathcal{I}_q\} \right. \\ \left. \times 1\{\text{individual } i \text{ observed at } t \ \& \ t - 2\} \mid t \right) = 0. \quad (23)$$

Finally, we match Medicaid utilization (take-up) rates. Once again, we divide individuals into 5 cohorts, match data from 5 waves, and stratify the data by permanent income. We combine the top two quintiles because in many cases no one in the top permanent income quintile is on Medicaid:  $Q_U = 4$ .

Let  $\bar{u}_{pqt}(\Delta, \chi)$  denote the model-predicted utilization rate for individuals in cohort  $p$  and permanent income group  $q$  at age  $t$ . Let  $u_{it}$  be the  $\{0, 1\}$  indicator that equals 1 when individual  $i$  receives Medicaid. The associated moment condition is

$$E \left( \left[ u_{it} - \bar{u}_{pqt}(\Delta_0, \chi_0) \right] \times 1\{p_i = p\} \times 1\{I_i \in \mathcal{I}_q\} \right. \\ \left. \times 1\{\text{individual } i \text{ observed at } t\} \mid t \right) = 0 \quad (24)$$

for  $p \in \{1, 2, \dots, P\}$ ,  $q \in \{1, 2, \dots, Q_U\}$ ,  $t \in \{t_1, t_2, \dots, t_T\}$ .

To summarize, the moment conditions used to estimate model with endogenous medical expenses consist of: the moments for asset medians described by equation (19); the moments for median medical expenses described by equation (20); the moments for the 90th percentile of medical expenses described by equation (21); the moments for the autocorrelations of logged medical expenses described by equations (22) and (23); and the moments for the Medicaid utilization rates described by equation (24). In the end, we have a total of  $J = 478$  moment conditions.

Suppose we have a dataset of  $I$  independent individuals that are each observed at up to  $T$  separate calendar years. Let  $\varphi(\Delta; \chi_0)$  denote the  $J$ -element vector of moment conditions described immediately above, and let  $\hat{\varphi}_I(\cdot)$  denote its sample analog. Letting  $\widehat{\mathbf{W}}_I$  denote a  $J \times J$  weighting matrix, the MSM estimator  $\hat{\Delta}$  is given by

$$\underset{\Delta}{\operatorname{argmin}} \frac{I}{1 + \tau} \hat{\varphi}_I(\Delta; \chi_0)' \widehat{\mathbf{W}}_I \hat{\varphi}_I(\Delta; \chi_0),$$

where  $\tau$  is the ratio of the number of observations to the number of simulated observations.

In practice, we estimate  $\chi_0$  as well, using the approach described in the main text. Computational concerns, however, compel us to treat  $\chi_0$  as known in the analysis that follows. Under regularity conditions stated in Pakes and Pollard [?] and Duffie and Singleton [?], the MSM estimator  $\hat{\Delta}$  is both consistent and asymptotically normally distributed:

$$\sqrt{I} \left( \hat{\Delta} - \Delta_0 \right) \rightsquigarrow N(0, \mathbf{V}),$$

with the variance-covariance matrix  $\mathbf{V}$  given by

$$\mathbf{V} = (1 + \tau)(\mathbf{D}'\mathbf{W}\mathbf{D})^{-1}\mathbf{D}'\mathbf{W}\mathbf{S}\mathbf{W}\mathbf{D}(\mathbf{D}'\mathbf{W}\mathbf{D})^{-1},$$

where:  $\mathbf{S}$  is the variance-covariance matrix of the data;

$$\mathbf{D} = \left. \frac{\partial \varphi(\Delta; \chi_0)}{\partial \Delta'} \right|_{\Delta=\Delta_0} \quad (25)$$

is the  $J \times M$  gradient matrix of the population moment vector; and  $\mathbf{W} = \text{plim}_{I \rightarrow \infty} \{\widehat{\mathbf{W}}_I\}$ . Moreover, Newey [?] shows that if the model is properly specified,

$$\frac{I}{1 + \tau} \hat{\varphi}_I(\hat{\Delta}; \chi_0)' \mathbf{R}^{-1} \hat{\varphi}_I(\hat{\Delta}; \chi_0) \rightsquigarrow \chi_{J-M}^2,$$

where  $\mathbf{R}^{-1}$  is the generalized inverse of

$$\begin{aligned} \mathbf{R} &= \mathbf{P}\mathbf{S}\mathbf{P}, \\ \mathbf{P} &= \mathbf{I} - \mathbf{D}(\mathbf{D}'\mathbf{W}\mathbf{D})^{-1}\mathbf{D}'\mathbf{W}. \end{aligned}$$

The asymptotically efficient weighting matrix arises when  $\widehat{\mathbf{W}}_I$  converges to  $\mathbf{S}^{-1}$ , the inverse of the variance-covariance matrix of the data. When  $\mathbf{W} = \mathbf{S}^{-1}$ ,  $\mathbf{V}$  simplifies to  $(1 + \tau)(\mathbf{D}'\mathbf{S}^{-1}\mathbf{D})^{-1}$ , and  $\mathbf{R}$  is replaced with  $\mathbf{S}$ .

But even though the optimal weighting matrix is asymptotically efficient, it can be biased in small samples. (See, for example, Altonji and Segal [?].) To check for robustness, we also use a “diagonal” weighting matrix, as suggested by Pischke [?]. This diagonal weighting scheme uses the inverse of the matrix that is the same as  $\mathbf{S}$  along the diagonal and has zeros off the diagonal of the matrix. This matrix delivers parameter estimates very similar to our benchmark estimates.

We estimate  $\mathbf{D}$ ,  $\mathbf{S}$ , and  $\mathbf{W}$  with their sample analogs. For example, our estimate of  $\mathbf{S}$  is the  $J \times J$  estimated variance-covariance matrix of the sample data. When estimating this matrix, we use sample statistics, so that  $a_{pqt}(\Delta, \chi)$  is replaced with the sample median for group  $pqt$ .

One complication in estimating the gradient matrix  $\mathbf{D}$  is that the functions inside the moment condition  $\varphi(\Delta; \chi)$  are non-differentiable at certain data points; see

equation (19). This means that we cannot consistently estimate  $\mathbf{D}$  as the numerical derivative of  $\hat{\varphi}_I(\cdot)$ . Our asymptotic results therefore do not follow from the standard GMM approach, but rather the approach for non-smooth functions described in Pakes and Pollard [?], Newey and McFadden [?] (section 7), and Powell [?].

To find  $\mathbf{D}$ , it is helpful to rewrite equation (19) as

$$\Pr \left( p_i = p \ \& \ I_i \in \mathcal{I}_q \ \& \ \text{individual } i \text{ observed at } t \right) \times \left[ \int_{-\infty}^{a_{pqt}(\Delta_0, \chi_0)} f \left( a_{it} \mid p, I_i \in \mathcal{I}_q, t \right) da_{it} - \frac{1}{2} \right] = 0. \quad (26)$$

It follows that the rows of  $\mathbf{D}$  are given by

$$\Pr \left( p_i = p \ \& \ I_i \in \mathcal{I}_q \ \& \ \text{individual } i \text{ observed at } t \right) \times f \left( a_{pqt} \mid p, I_i \in \mathcal{I}_q, t \right) \times \frac{\partial a_{pqt}(\Delta_0; \chi_0)}{\partial \Delta'}. \quad (27)$$

In practice, we find  $f(a_{pfqt}|p, q, t)$ , the conditional p.d.f. of assets evaluated at the median  $a_{pqt}$ , with a kernel density estimator written by Koning [?]. The gradients for equations (20) and (21) are found in a similar fashion.

## Appendix B: Demographic Transition Probabilities in the HRS/AHEAD

Let  $h_t \in \{0, 1, 2, 3\}$  denote death ( $h_t = 0$ ) and the 3 mutually exclusive health states of the living (nursing home = 1, bad = 2, good = 3, respectively). Let  $x$  be a vector that includes a constant, age, permanent income, gender, and powers and interactions of these variables, and indicators for previous health and previous health interacted with age. Our goal is to construct the likelihood function for the transition probabilities.

Using a multivariate logit specification, we have, for  $i \in \{1, 2, 3\}$ ,  $j \in \{0, 1, 2, 3\}$ ,

$$\begin{aligned} \pi_{ij,t} &= \Pr(h_{t+1} = j \mid h_t = i) \\ &= \gamma_{ij} / \sum_{k \in \{0,1,2,3\}} \gamma_{ik}, \\ \gamma_{i0} &\equiv 1, \quad \forall i, \\ \gamma_{1k} &= \exp(x\beta_k), \quad k \in \{1, 2, 3\}, \\ \gamma_{2k} &= \exp(x\beta_k), \quad k \in \{1, 2, 3\}, \\ \gamma_{3k} &= \exp(x\beta_k), \quad k \in \{1, 2, 3\}, \end{aligned}$$

where  $\{\beta_k\}_{k=0}^3$  are sets of coefficient vectors and of course  $\Pr(h_{t+1} = 0 \mid h_t = 0) = 1$ .

The formulae above give 1-period-ahead transition probabilities,  $\Pr(h_{t+1} = j | h_t = i)$ . What we observe in the AHEAD dataset, however, are 2-period ahead probabilities,  $\Pr(h_{t+2} = j | h_t = i)$ . The two sets of probabilities are linked, however, by

$$\begin{aligned} \Pr(h_{t+2} = j | h_t = i) &= \sum_k \Pr(h_{t+2} = j | h_{t+1} = k) \Pr(h_{t+1} = k | h_t = i) \\ &= \sum_k \pi_{kj,t+1} \pi_{ik,t}. \end{aligned}$$

This allows us to estimate  $\{\beta_k\}$  directly from the data using maximum likelihood.
